

The Telescope Playground

What are the optimal positions of the lenses of a Galilean, a Keplerian and a terrestrial telescope?

Let's find out!

Material

2x base plate 1x4 (50x200 mm)
2x lens cube 1x1, $f=+50$ mm (A)
1x lens cube 1x1, $f=-50$ mm (B)
1x lens cube 1x1, $f=+100$ mm (C)

Theory

Telescopes

A refracting telescope (also called a refractor) is a type of optical telescope that uses lenses to form an image. Refractors were the earliest type of optical telescope. The first practical refracting telescopes appeared in the Netherlands about 1608. All refracting telescopes use the same principles. The combination of an objective lens and eyepiece lens is used to gather more light than the human eye is able to collect on its own, focus it, and present the viewer with a brighter, clearer, and magnified virtual image.

Galilean telescope

The design Galileo Galilei used in 1609 is commonly called a Galilean telescope. It used a convergent (plano-convex) objective lens and a divergent (plano-concave) eyepiece lens [Galileo, 1610]. In a Galilean telescope, the image is non-inverted, since the design has no intermediary focus.

Figure 1: Galileo observing the planets with his telescope

Galileo's best telescope magnified objects about 30 times. Because of flaws in its design, such as the shape of the lens and the narrow field of view, the images were blurry and distorted. Despite these flaws, the telescope was still good enough for Galileo to explore the sky. The Galilean telescope could view the phases of Venus, and was able to see craters on the Moon and four moons orbiting Jupiter.

Figure 2: Scheme of Galilean telescope

The concave lens L_2 serves as an eyepiece and is placed in front of the focal plane of the objective lens L_1 in such a way that the back focal point F'_1 of L_1 coincides with the focal point F_2 of L_2 . The distance between the principle planes of objective and eyepiece is $f_1 - |f_2|$. Besides $F'_1 = F_2$.

We then observe a virtual non-inverted magnified image of the observed object.

For small angles the (angular) magnification is given by $\Gamma_L = f_1 / |f_2|$.

Keplerian telescope

The Keplerian telescope, invented by Johannes Kepler in 1611, is an improvement on Galileo's design. It uses a convex lens as the eyepiece instead of Galileo's concave one. The advantage of this arrangement is that the rays of light emerging from the eyepiece are converging. This allows for a much wider field of view and greater eye relief, but the image for the viewer is inverted. Considerably higher magnifications can be reached with this design, but to overcome aberrations the simple objective lens needs to have a very high ratio of focal distances (Johannes Hevelius built one with a 46-metre focal length, and even longer tubeless "aerial telescopes" were constructed).

Figure 3: Scheme of Keplerian telescope

Keplerian telescope is composed of two convex lenses. The objective lens L_1 , focal distance f_1 , creates an image which is then observed through the eyepiece lens L_2 with focal distance f_2 . The distance between the principle planes of objective and eyepiece is $f_1 + f_2$. Besides $F'_1 = F_2$.

We then observe a virtual inverted magnified image of the observed object.

For small angles the (angular) magnification is given by $\Gamma_L = f_1 / f_2$

Figure 4: The 46-meters long Keplerian telescope built by Johannes Hevelius

Terrestrial telescope

A terrestrial telescope is a telescope which, unlike most telescopes used for astronomical purposes, contains an arrangement of lenses presenting an non-inverted image to the observer, suitable for observation of objects on the Earth's surface.

Figure 5: Scheme of terrestrial telescope

A terrestrial telescope is, in a way, just a Keplerian telescope modified for terrestrial observation. An inverting lens is placed between the objective and the eyepiece and it inverts the image in the focal plane of the objective, so it's flipped when viewed through the eyepiece.

The objective lens L_1 , focal distance f_1 , creates an image in its back focal plane. The inverting lens L_i has a focal distance f_i and is placed in the distance of $f_1 + 2f_i$ behind the objective. It creates an inverted image (magnification -1) in the distance of $2f_i$ which is then observed through the eyepiece lens L_2 with focal distance f_2 . The distance between inverting lens and eyepiece is $2f_i + f_2$. The whole system, from objective is therefore $f_1 + f_2 + 4f_i$ long.

The inverting lens doesn't contribute to the magnification and for small angles the magnification is calculated the same way as in a Keplerian telescope, given by $\Gamma_L = f_1 / f_2$

Tasks

Hint: You'll get the best optical performance if all the arrows point in the same direction.

Task 0:

Explore what each lens does alone. Look through the lenses A, B and C both to a long distance (from a window) and to a short distance (on this manual). Move the lens closer and further from your eye and see how it changes the image.

Lenses A and C provide magnified / de-magnified image.

Through lens A the far-away object appears to be bigger / smaller than through lens C.

When used as a magnifying glass (for short distance), lens A has to be held closer / further from the paper than lens C. The text is more magnified by lens A / C.

Lens B always / for far-away objects / for near objects provides magnified / de-magnified and inverted / non-inverted image.

Task 1:

Build a Galilean telescope using two lenses, one as an objective, the second one as an eyepiece

I choose a cube as the objective and cube as then eyepiece. The magnification of my Galilean telescope is I observe an image of the object which is inverted / non-inverted.

Write the letters of the cubes to the positions in which you put them on the base plate. The viewer is on the right side and he's looking in the direction of the arrow.

Task 2:

Build a Keplerian telescope using two lenses, one as an objective, the second one as an eyepiece

I choose a cube as the objective and cube as then eyepiece. The magnification of my Keplerian telescope is I observe an image of the object which is inverted / non-inverted.

Write the letters of the cubes to the positions in which you put them on the base plate. The viewer is on the right side and he's looking in the direction of the arrow.

Task 3:

Build a terrestrial telescope using three lenses, one as an objective, the second one as an eyepiece and the third as an inverting lens.

I choose a cube as the objective and cube as then eyepiece. As the inverting lens I used cube The magnification of my terrestrial telescope is I observe an image of the object which is inverted / non-inverted.

Write the letters of the cubes to the positions in which you put them on the base plate. The viewer is on the right side and he's looking in the direction of the arrow.
